Abstract

The line simplification problem is an old and well-studied problem in cartography. Although there are several efficient algorithms to compute a simplification within a specified error bound, there seem to be no algorithms that perform line simplification in the context of other geographical objects. Given a polygonal line and a set of extra points, we present a nearly quadratic time algorithm for line simplification that guarantees (i) a maximum error $\epsilon$, (ii) that the extra points remain on the same side of the output chain as of the original chain, and (iii) that the output chain has no self-intersections. The algorithm is applied as the main subroutine for subdivision simplification.

1 Introduction

The line simplification problem is a well-studied problem in various disciplines including geographic information systems, digital image analysis, and computational geometry (see the references). Often the input is a polygonal chain and a maximum allowed error $\epsilon$, and methods are described to obtain another polygonal chain with fewer vertices that lies at distance at most $\epsilon$ from the original polygonal chain. Some methods yield chains of which all vertices are also vertices of the input chain, other methods yield chains where other points can be vertices as well. Another source of variation on the basic problem is the error measure that is used. Well known criteria are the parallel strip error criterion, Hausdorff distance, Fréchet distance, areal displacement, and vector displacement. Besides geometric error criteria, in geographic information systems one can also use criteria based on the geographic knowledge, or on perception [Mark '89].

The motivation for studying these simplification problems is twofold. Firstly, polygonal lines at a high level of detail consume a lot of storage space. In many situations a high level of detail is unnecessary or even unwanted. Secondly, when objects are described at a high level of detail, operations performed on them tend to...
be slow. An example where this problem can be severe is in the animation of moving objects.

Our motivation for studying the line simplification problem stems from reducing the storage space needed to represent a map in a geographic information system. We assume the map is modelled as a subdivision of the plane or a rectangular region thereof. In this application the main consideration is the reduction of the complexity of the subdivision. The processing time may be a little higher, but within reason. The size of the subdivision is a permanent cost in a geographic information system, whereas the processing time is spent only once in many applications.

One of the most important requirements of subdivisions for maps is that they be simple. No two edges of the subdivision may intersect, except at the endpoints. This poses two extra conditions on the line simplification method. Firstly, when a polygonal chain is reduced in complexity, the output polygonal chain must be a simple polygonal chain. Several of the line simplification methods described before don't satisfy this constraint [Chan & Chin '92, Cromley '88, Douglas & Peucker '73, Eu & Toussaint '94, Hershberger & Snoeyink '92, Imai & Iri '88, Li & Openshaw '92, Melkman & O'Rourke '88]. The second condition that need be satisfied is that the output chain does not intersect any other polygonal chain in the subdivision. In other words, the simplification method must respect the fact that the polygonal chain to be simplified has a context. Usually the context is more than just the other chains in the subdivision. On a map with borders of countries and cities, represented by polygonal chains and points, a simplification method that does not respect the points can yield a subdivision in which cities close to the border lie in the wrong country. In Figure 1, Maastricht has moved from the Netherlands to Belgium. Canterbury has moved into the sea, and at the top of the border between The Netherlands and Germany, two borders intersect. Such topological errors in the simplification lead to inconsistencies in geographic information systems.

In this paper we will show that both conditions can be enforced after reformulating the problem into an abstract geometric setting. This is quite different from the approach reported in [Zhan & Mark '93], who have done a cognitive study on conflict resolution due to simplification. They accept that the simplification process may lead to conflicts (such as topological errors) and try to patch up the problems afterwards. We avoid conflicts from the start by using geometric algorithms. These algorithms are fairly easy to implement.
The remainder of this paper is organized as follows. Section 2 discusses our approach to the subdivision simplification, and identifies the main subtask: a new version of line simplification. Section 3 describes the approach of Imai and Iri for the standard line simplification problem. In Section 4 we adapt the algorithm for the new version of line simplification. In Section 5 the conclusions are given.

2 Subdivision simplification

Let $S$ be a subdivision that models a map, and let $P$ be a set of points that model special positions inside the regions of the map. The subdivision $S$ consists of vertices, edges and cells. The degree of a vertex is the number of edges incident to it. A vertex of degree one is a leaf, a vertex of degree two is an interior vertex, and a vertex of degree at least three is a junction. See Figure 2. Generally the number of leafs and junctions is small compared to the number of interior vertices. Any sequence of vertices and edges starting and ending at a leaf or junction, and with only interior vertices in between, is called a polygonal chain, or simply a chain. For convenience we also consider a cycle of interior vertices as a chain, where we choose one of the vertices as start and end vertex of the chain.

Subdivision simplification can now be performed as follows. Keep the positions of all leafs and junctions fixed, and also the positions of the points in $P$. Replace every chain between a start and end vertex by a new chain with the same start and end vertex but with fewer interior vertices. If $C$ is a polygonal chain, then we require from its simplification $C'$:

1. No point on the chain $C$ has distance more than a prespecified error tolerance to its simplification $C'$.
2. The simplification $C'$ is a chain with no self-intersections.
3. The simplification $C'$ may not intersect other chains of the subdivision.
4. All points of $P$ lie to the same side of $C'$ as of $C$.

Let's take a closer look at the last requirement. The chain $C$ is part of a subdivision that, generally, separates two cells of the subdivision. In those two cells there may be points of $P$. The simplified chain between the start vertex and the end vertex will also separate two cells of the subdivision, but these cells have a slightly different shape. The fourth requirement states that the simplified chain $C'$ must have the same subsets of points in those two cells.

The first requirement will be enforced by using and extending a known algorithm that guarantees a maximum error $\epsilon$. The other three requirements are enforced by the way we extend the known algorithm. Roughly spoken, the simplified chain consists of a sequence of edges that bypass zero or more vertices of the input chain. We
will develop efficient tests to determine whether edges in the simplified chain leave points of $P$ to the wrong side or not. The second requirement, finally, doesn't add to the complexity of the algorithm. When applying the simplification algorithm to some chain of the subdivision, we temporarily add to the set $P$ of points all vertices of other chains of the subdivision. One can show that—since $C'$ has the vertices of other chains to the same side as $C$—the simplified chain $C'$ won't intersect any other chain of the subdivision. A simplified chain that has the points of $P$ to the correct side and doesn't intersect other chains in the subdivision is a consistent simplification.

A disadvantage of adding the vertices to the point set $P$ is that $P$ can become quite large, which will slow down the algorithm. There are two observations that can help reduce the number of points that need be added to $P$. Firstly, we only have to take the vertices of the chains that bound one of the two cells separated by the chain we are simplifying. Secondly, it is easy to show that only points inside the convex hull of the chain that is being simplified could possibly end up to the wrong side. So we only have to use points of $P$ and vertices of other chains that lie inside this convex hull. In Figure 2, the chain that represents the border between the Netherlands and Germany is shown with its convex hull (dashed) and some cities close to the border (squares). No other chains intersect the convex hull, and only the cities Emmen, Enschede, Kleve and Venlo must be considered when simplifying the chain.

It remains to solve a new version of the line simplification problem. Namely, one where there are extra points which must be to the same side of the original and the simplified chain. For this problem we will develop an efficient algorithm in the following sections. It takes $O(n(n + m)\log n)$ time for a polygonal chain with $n$ vertices and $m$ extra points. This will lead to:

**Theorem 1** Given a planar subdivision $S$ with $N$ vertices and $M$ extra points, and a maximum allowed error $\epsilon > 0$, a simplification of $S$ that satisfies the four requirements stated above can be computed in $O(N(N + M)\log N)$ time in the worst case.

The close to quadratic time behavior of the algorithm is the time needed in the worst case. Therefore, the algorithm may seem too inefficient for subdivisions with millions of vertices. A better analysis that also incorporates some realistic assumptions will show that the time taken in practice is much lower. It will also depend on the sizes of the chains in the subdivision, the number of extra points inside the convex hull of a chain, and the shapes of the chains themselves.

### 3 Preliminaries on line simplification

We describe the line simplification algorithm in [Imai & Iri '88], upon which our method is based. Let $v_1,\ldots,v_n$ be the input polygonal chain $C$. A line segment $v_i v_j$ is called a shortcut for the subchain $v_i,\ldots,v_j$. A shortcut is allowed if and only if the error it induces is at most some prespecified positive real value $\epsilon$, where the error of a shortcut $v_i v_j$ is the maximum distance from $v_i v_j$ to a point $v_k$, where $i < k < j$.

We wish to replace $C$ by a chain consisting of allowed shortcuts. In this paper we don't consider simplifications that use vertices other than those of the input chain.

Let $G$ be a directed acyclic graph with as the node set $V = \{v_1,\ldots,v_n\}$. The arc set $E$ contains $(u_i, v_j)$ if and only if $i < j$ and the shortcut $v_i v_j$ is allowed. The graph $G$ can be constructed with a simple algorithm in $O(n^3)$ time and $G$ has size $O(n^2)$.

A shortest path from $v_1$ to $v_n$ in $G$ corresponds to a minimum vertex simplification of the polygonal chain. Using topological sorting, the shortest path can be computed in time linear in the number of nodes and arcs of $G$ [Cormen et al. '90]. Therefore, after the construction of $G$, the problem can be solved in $O(n^2)$ time. We remark that
the approach can always terminate with a valid output, because the original polygonal line is always a valid output (though hardly a simplification). The bottleneck in the efficiency is the construction of the graph $G$. In [Melkman & O'Rourke '88] it was shown that $G$ can be computed in $O(n^2 \log n)$ time, reducing the overall time bound to $O(n^2 \log n)$ time. In [Chan & Chin '92] an algorithm was given to construct $G$ in $O(n^2)$ time. This is optimal in the worst case because $G$ can have $\Theta(n^2)$ arcs. We explain their algorithm briefly.

One simple but useful observation is that the error of a shortcut $v_i v_j$ is the maximum of the errors of the half-line starting at $v_i$ and containing $v_j$, and the half-line starting at $v_j$ and containing $v_i$. Denote these half-lines by $l_{ij}$ and $l_{ji}$, respectively. We construct a graph $G_1$ that contains an arc $(v_i, v_j)$ if and only if the error of $l_{ij}$ is at most $\epsilon$, and a graph $G_2$ which contains an arc $(v_i, v_j)$ if and only if the error of $l_{ji}$ is at most $\epsilon$. To obtain the graph $G$, we let $(v_i, v_j)$ be an arc of $G$ if and only if $(v_i, v_j)$ is an arc in both $G_1$ and $G_2$. The problem that remains is the construction of $G_1$ and $G_2$ which boils down to determining whether the errors of the half-lines is at most $\epsilon$ or not. We only describe the case of half-lines $l_{ij}$ for all $1 \leq i < j \leq n$; the other case is completely analogous.

The algorithm starts by letting the vertices $v_1, \ldots, v_n$ in turn be $v_1$. Given $v_i$, the errors of all half-lines $l_{ij}$ with $j > i$ are determined in the order $l_{i(i+1)}, l_{i(i+2)}, \ldots, l_{in}$ as follows. If we associate with $v_k$ a closed disk $D_k$ centered at $v_k$ and with radius $\epsilon$, then the error of $l_{ij}$ is at most $\epsilon$ if and only if $l_{ij}$ intersects all disks $D_k$ with $i \leq k \leq j$. Hence, the algorithm maintains the set of angles of half-lines starting at $v_i$ that intersect the disks $D_i, \ldots, D_j$. Initially, the set contains all angles $[-\pi, \pi]$. The set of angles will always be one interval, that is, the set of half-lines with error at most $\epsilon$ up to some vertex form a wedge with $v_i$ as the apex. Updating the wedge takes only constant time when we take the next $v_j$, and the algorithm may stop the inner iteration once the wedge becomes empty.

With the approach sketched above, the graph construction requires $O(n^2)$ time in the worst case [Chan & Chin '92].

Figure 3: Deciding which arcs $(v_i, v_j)$ with $j > i$ are accepted to $G_1$. Only $(v_i, v_{i+1})$ and $(v_i, v_{i+3})$ will be accepted.

The wedge need not be reduced. Vertex $v_{i+4}$ lies outside the wedge so $(v_i, v_{i+4})$ is not accepted.

The wedge becomes empty so no other arc $(v_i, v_j)$ will be accepted.
4 Consistent simplification of a chain

In this section we generalize the line simplification algorithm just described to overcome the two main drawbacks: it doesn’t necessarily yield a simple chain and it doesn’t leave extra points to the correct side. We only discuss the simplification of \( x \)-monotone chains. There are several ways to generalize our algorithms to the case of arbitrary chains. At the end of this section we sketch one method briefly; for details and extensions we refer to the full version of this paper.

A polygonal chain is \( x \)-monotone if any vertical line intersects it in at most one point. In other words, an \( x \)-monotone polygonal chain is a piecewise linear function defined over an interval. It is easy to see that any simplification of an \( x \)-monotone polygonal chain is also an \( x \)-monotone polygonal chain. Let \( C \) be an \( x \)-monotone simple polygonal chain with vertices \( v_1, \ldots, v_n \). We denote the subchain of \( C \) between vertices \( v_i \) and \( v_j \) by \( C_{i,j} \). Let \( P \) be a set of \( m \) points \( p_1, \ldots, p_m \). From the definition of consistency we observe:

**Lemma 1** \( C' \) is a consistent simplification of \( C \) with respect to \( P \) if and only if no point of \( P \) lies in a bounded region formed by \( C \) and \( C' \).

Let \( Q_{i,j} \) be the not necessarily simple polygon bounded by \( C_{i,j} \) and the edge \( v_i v_j \), so \( Q_{i,j} \) contains \( j - i \) edges of \( C \) and one more edge \( v_i v_j \). This last edge may intersect other edges of \( Q_{i,j} \). The general approach we take is to compute a graph \( G_3 \) with \( \{v_1, \ldots, v_n\} \) as the node set, and an arc \((v_i, v_j)\) whenever the bounded regions of \( Q_{i,j} \) contain no points of \( P \). So we don’t consider the error of the shortcut \( v_i v_j \). This is done only later, when we determine the graph \( G \) on which the shortest path algorithm is applied. The graph \( G \) can be determined from the graphs \( G_1 \) and \( G_2 \) from the previous section, and the graph \( G_3 \) defined above. \( G \) has an arc \((v_i, v_j)\) if and only if \((v_i, v_j)\) is an arc in each of the graphs \( G_1 \), \( G_2 \), and \( G_3 \).

To compute arcs of the graph \( G_3 \), we consider for each vertex \( v_i \), the shortcuts \( v_i v_j \). We keep \( v_i \) fixed, and show that all arcs \((v_i, v_j)\) with \( i < j \leq n \) can be computed in \( O((n + m) \log n) \) time. The first step is to sort the shortcuts \( v_i v_{i+1}, \ldots, v_i v_n \) by slope. Here we consider the shortcuts to be directed away from \( v_i \). Since \( C \) is \( x \)-monotone, all shortcuts are directed towards the right. The shortcuts are stored in a list \( L \).

The second step of the algorithm is to locate all tangent segments from \( v_i \). We define a shortcut \( v_i v_j \) to be tangent if \( v_{j-1} \) and \( v_{j+1} \) lie in the same closed half-plane bounded by the line through \( v_i \) and \( v_j \), and \( i + 1 < j < n \). The shortcut \( v_i v_n \) is always considered to be tangent. The tangent shortcuts in Figure 4 are \( v_i v_{i+5}, v_i v_{i+6}, v_i v_{i+7}, \) and \( v_i v_{i+9} \). A tangent shortcut \( v_i v_j \) is minimal (in slope) if \( v_{j-1} \) lies above the line through \( v_i \) and \( v_j \). If \( v_{j-1} \) lies below that line, then it is maximal (in slope), and if \( v_{j-1} \) lies on the line it is degenerate (it has length zero). The tangent splitter is the line segment \( w_i v_j \) defined as the maximal closed subsegment of \( v_i v_j \) that does not intersect \( C \) in a point interior to \( v_i v_j \). So the point \( w_i \) is an intersection point of the chain \( C \) and the shortcut \( v_i v_j \), and the one closest to \( v_j \) among these, see Figure 4. If \( v_{j-1} \) lies on the shortcut \( v_i v_j \) then \( v_i v_j \) degenerates to the point \( v_j \). A tangent splitter is minimal, maximal, or degenerate when the tangent shortcut is.
Let $\gamma(1), \ldots, \gamma(r)$ be the nondegenerate tangents. The corresponding set of tangent splitters and $C$ together define a subdivision $S$, of the plane of linear size, see Figure 5. The subdivision has $r$ bounded cells, each of which is bounded by pieces of $C$ and one or more minimal or maximal tangent splitters.

For every cell of $S$, consider the vertex with highest index bounding that cell. This vertex must define a tangent splitter, so it is one of $\gamma(1), \ldots, \gamma(r)$. Assume it is $\gamma(b)$. Then we associate with that cell the number $b$. The subdivision and its numbering have some useful properties.

**Lemma 2** Every bounded cell of the subdivision $S$ is $\theta$-monotone with respect to $v_i$, that is, any half-line rooted at $v_i$ intersects any bounded cell of $S$ in zero or one connected components.

**Lemma 3** Every bounded cell of the subdivision $S$ has one connected subchain of $C$ where half-lines rooted at $v_i$ leave that cell.

**Lemma 4** Any directed half-line from $v_i$ intersects cells in order of increasing number.

The points $w_j$ can be found in linear time as follows. Traverse $C$ from $v_i$ towards $v_n$. At every vertex $v_j$ for which $\overrightarrow{w_j}$ is tangent (and non-degenerate), walk back along $C$ until we reach $v_i$ or find an intersection of $\overrightarrow{w_j}$ with $C$. In the latter case, the fact that $C$ is $x$-monotone guarantees that the point we found is the rightmost intersection, and thus it must be $w_i$. Then we continue the traversal forward at $v_j$ towards $v_n$. This approach would take quadratic time, but we use the following idea to bring it down to linear. Next time we walk back to compute the next tangent splitter, we use previous tangent splitters walk back quickly. For a new maximal tangent splitter we only use previously found maximal tangent splitters, and for a new minimal tangent splitter we only use minimal ones. One can show that the skipped part of $C$ never contains the other endpoint of the tangent splitter we are looking for.

The total cost of all backward walks is $O(n)$, which can be seen as follows. During the walks back we visit each vertex which is not incident to a splitter at most twice (once when locating $w_j$ for a maximal tangent splitter $\overrightarrow{w_j}w_j$, and once for a minimal tangent splitter). Each splitter is used as quick walk backwards only once. So we can charge the cost of the backwards walks to the $O(n)$ vertices of $C$ and the $O(n)$ tangent splitters.

The third step of the algorithm is to distribute the points of $P$ among the cells of the subdivision $S$. Either by a plane sweep algorithm where a line rotates about $v_i$, or by preprocessing $S$ for point location, this step requires $O((n + m) \log n)$ time [Preparata & Shamos '85]. All points of $P$ that don't lie in a bounded cell of $S$ can be discarded; they cannot be in a bounded region of the polygon $Q_{\gamma}$ for any shortcut $\overrightarrow{w_j}$. But we can discard many more points. For every cell of $S$, consider the tangent splitter with the vertex of highest index. If that tangent splitter is minimal, we discard all points in it except for the point $p$ that maximizes the slope of the directed segment $\overrightarrow{w_j}p$, see Figure 6. Similarly, if the tangent splitter with highest index is maximal, we discard all points in the cell except for the point $p$ that minimizes the slope of the directed segment $\overrightarrow{w_j}p$. Now every cell of $S$ contains at most one point of $P$. 85
Lemma 5  Any shortcut $v_i v_j$ is consistent with the subchain $C_{ij}$ with respect to $P$ if and only if it is consistent with respect to the remaining subset of points of $P$.

In the fourth step of the algorithm we decide which shortcuts $v_i v_j$ are consistent and should be present in the graph $G_3$ in the form of an arc $(v_i, v_j)$. We treat the cells of $S_1$ in the order of increasing associated number. When treating a cell, we will discard any shortcut $v_i v_j$ that has not yet been accepted and is inconsistent with respect to the one remaining point of $P$ in that cell (if any). Then we accept those shortcut $v_i v_j$ that have $v_j$ on the boundary of the cell and have not yet been discarded. For discarding shortcuts, we use the order of shortcuts by slope as stored in the list $L$ in the first step. For accepting shortcuts, we use the order along the chain $C$.

In more detail, the fourth step is performed as follows. Iterate through the cells $s_1, \ldots, s_t$ of $S_1$. Suppose that we are treating $s_b$. If there is no point of $P$ in the cell $s_b$, then we skip the discarding phase and continue immediately with the accepting phase. Otherwise, let $p_b$ be the point of $P$ that lies in $s_b$. Assume first that the tangent splitter $\gamma(b)$ is minimal. Consider the list $L$ of shortcuts starting at the end where shortcuts have the smallest slope. Repeatedly test whether the first shortcut at that end of the list $L$ has larger or smaller slope than the line segment $v_i p_b$. If the shortcut has smaller slope, then discard that shortcut by removing it from $L$. If the shortcut has larger slope, stop the discarding. In Figure 7, the shortcuts that are subsequently discarded when cell $s_1$ is treated are $v_1 v_6, v_1 v_3, v_1 v_4, v_1 v_5, v_1 v_6$, and $v_1 v_8$. If the tangent splitter is maximal then similar actions are taken, but on the end of the list $L$ where the shortcuts have largest slope.

Lemma 6  Every discarded shortcut $v_i v_j$ is inconsistent with the subchain $C_{ij}$ with respect to the points of $P$.

After the discarding phase the accepting phase starts. For all vertices $v_j$ with $\gamma(b - 1) < j \leq \gamma(b)$ on $C$, if the shortcut $v_i v_j$ is still in $L$, accept it by removing it from $L$ and letting $(v_i, v_j)$ be an arc in the graph $G_3$.

Lemma 7  Any accepted shortcut $v_i v_j$ is consistent with the subchain $C_{ij}$ with respect to the points of $P$.

The fourth step requires $O(n)$ time, which can be seen as follows. For each cell, we spend $O(d + 1)$ time for discarding if $d$ segments in $L$ are discarded. This is obvious because discarding is simply removing from an end of the list $L$. To accept efficiently,
we maintain pointers between the list $L$ and the chain $C$ so that shortcuts—once they are accepted—can be removed from $L$ in constant time. Then we spend $O(a + 1)$ time if $a$ shortcuts are accepted. Since any shortcut is discarded or accepted once, and there are a linear number of cells in $S_i$, it follows that the fourth step takes linear time.

If we perform the above steps for all vertices $v_i$, then combine the obtained graph $G_3$ with the graphs $G_1$ and $G_2$ (as defined in the previous section) to create the graph $G$, we can conclude with the following result.

**Theorem 2** Given an $x$-monotone polygonal chain $C$ with $n$ vertices, a set $P$ of $m$ points, and an error tolerance $\epsilon > 0$, it is possible to compute the minimum link simplification of $C$ that is consistent with respect to $P$ and that approximates $C$ within the error tolerance $\epsilon$ in $O(n(n + m) \log n)$ time.

The simplification is also simple, but this is automatic because every $x$-monotone polygonal chain is simple. There are, however, several ways to generalize our results so that they can be applied to arbitrary, not $x$-monotone chains. Let $C$ be such a chain, and let $v_i$ be a vertex for which we wish to compute good shortcuts. One can determine a subchain $v_i, \ldots, v_k$ of $C$ that is $x$-monotone after rotation of $C$. To assure that shortcuts $v_i v_j$ with $j < k$ don’t intersect edges before $v_i$ or after $v_k$ in the chain $C$, we add the vertices before $v_i$ and after $v_k$ to the set $P$ of extra points. Then we run the algorithm of this section. One can show that any shortcut $v_i v_j$ with $j < k$ that is consistent with respect to the extra points must be a consistent shortcut for the whole chain $C$, and it cannot intersect any edges of $C$. The generalized algorithm also runs in close to quadratic time.

5 Conclusions

This paper has shown that it is possible to perform line simplification in such a way that topological relations are maintained. Points lie above the original chain will also lie above the simplified chain, and points that lie below will remain below. Furthermore, the line simplification algorithm can guarantee a user specified upper bound on the error, and the output chain has no self-intersections. The method leads to an efficient algorithm for subdivision simplification without creating any false intersections. To obtain these results, we relied on techniques from computational geometry. We have also developed more advanced algorithms for simplifying arbitrary chains that allow of more reduction than the algorithm based on the idea described here. These extensions are given in the full paper.

With ideas similar to ours, some other line simplification methods can also be adapted to be consistent with respect to a set of tag points. In particular, the algorithm in [Douglas & Peucker ’73] can be extended.

The given algorithm takes $O(n(n + m) \log n)$ time to perform the simplification for a chain with $n$ vertices and $m$ extra points. This leads to an $O(N(N + M) \log N)$ time (worst case) algorithm for simplifying a subdivision with $N$ vertices and $M$ extra points. There are many ideas that can be used to speed up the algorithm in practice. Therefore, we expect that the algorithm performs well in many situations, but probably not in real-time applications. Much depends on whether the quadratic time behavior of the method will actually show up on real world data.

The study in this paper has been theoretical of nature. Yet the given algorithms should be fairly straightforward to implement. We plan to implement our algorithm and run it on real world data. This way we can find out in which situations the efficiency of the method is satisfactory.
